**Abstract.** Heteropteran insects are characterized by holokinetic chromosomes, and, in most species, the post-reductional meiotic division of sex chromosomes and the presence of one chiasma per bivalent. The Reduviidae have a modal diploid autosomal number of 20 with a range between 12 to 34, and both simple and multiple sex chromosome systems (XY/XX, X<sub>0</sub>/XX, X<sub>n</sub>Y/X<sub>n</sub>X<sub>n</sub>). Within this family cytogenetic reports on 127 species belonging to 11 subfamilies are available. Stenopodainae (10 species) have a diploid autosomal number of 20/22 plus different multiple sex chromosome systems; in Harpactorinae 33 species belonging to 18 genera have been cytogenetically analysed, and the modal diploid number of the subfamily is 2n=28=24+X<sub>1</sub>X<sub>2</sub>X<sub>3</sub>Y (male). In the present work we analyse the karyotype and male meiosis of *Stenopoda cinerea* Laporte, 1833 (2n=25=20+X<sub>1</sub>X<sub>2</sub>X<sub>3</sub>X<sub>4</sub>Y) (male) (Stenopodainae); *Zelus* sp. prope *leucogrammus* (Perty, 1834) (2n=26=24+XY) (male), *Apiomerus lanipes* (Fabricius, 1803) (2n=24=22+XY) (male), *Cosmoclopius nigroannulatus* (Stål, 1860) and *C. poecilus* (Herrich-Schaeffer, 1848) (2n=28/30=24+X<sub>1</sub>X<sub>2</sub>X<sub>3</sub>Y/24+X<sub>1</sub>X<sub>1</sub>X<sub>2</sub>X<sub>2</sub>X<sub>3</sub>X<sub>3</sub>) (male/female) (Harpactorinae). Considering the cytogenetic characteristics of Reduviidae two evolutionary trends can be observed within the family: a reduction in the number of autosomes through fusion mechanisms, and an increase in the number of sex chromosomes through fragmentations (multiple systems). Furthermore, the presence of multiple sex chromosome systems is much more frequent in Harpactorinae and Stenopodainae than in the other subfamilies. These cytogenetic trends support a previously proposed phylogeny based on morphological, ecological and behavioural traits (Ambrose, 1999).

**Key words:** Heteroptera, Reduviidae, holokinetic chromosomes, karyotype evolution, sex chromosomes.

## INTRODUCTION

Reduviidae are the largest family of predaceous land Heteroptera, and contain about 930 genera and 6500 species placed in 22 subfamilies. The size of these predatory assassin bugs ranges from relatively small and extremely delicate insects of

only a few millimetres in length, such as members of the genus *Empicoris* Wolff, 1811 (Emesinae) to very large and formidable animals such as *Arilus* Hahn, 1831 (Harpactorinae), which may attain a length of nearly 40 mm (Schuh, Slater, 1995). Most reduviids are general predators and they occur worldwide. Being larger than many other preda-

ceous land bugs and encompassing in their development a greater range of size, reduviid predators consume not only more prey but also a wider array of prey. Hence, they are important mortality factors and should be conserved and augmented for their utilization in biocontrol programs. Within Reduviidae the species belonging to Triatominae are distinctive for their blood-sucking habits, and several of them are vectors or potential vectors of Chagas' disease (Schaefer, Panizzi, 2000).

Cytogenetic reports are available for 122 species of Reduviidae. Apart from the general fea-

tures of heteropteran insects (holokinetic chromosomes, post-reductional meiotic division of sex chromosomes, one chiasma per bivalent in male meiosis), reduviids are characterized by a modal diploid number of autosomes of 20 with a range between 10 to 34, and both simple and multiple sex chromosome systems: XY/XX (46.34%) and X<sub>n</sub>Y/X<sub>n</sub>X<sub>n</sub> (51.22%); only 3 species have an X0/XX system (Ueshima, 1979).

In the present work we studied the karyotype and male meiosis of *Stenopoda cinerea* Laporte, 1833 (Stenopodainae), *Zelus* sp. prope *leuco-*

**Table 2.** Number, date and provenance of adult male and female specimens.

*grammus* (Perty, 1834), *Apiomerus lanipes* (Fabricius, 1803), *Cosmoclopius nigroannulatus* (Stål, 1860) and *C. poecilus* (Herrich-Schaeffer, 1848) (Harpactorinae). Previous cytogenetic studies in the subfamily Stenopodainae report a diploid number of 20/22 autosomes plus different multiple sex chromosome systems (Table 1). Within Harpactorinae 29 species belonging to 16 genera have been cytogenetically analysed, and the modal diploid autosomal number of the subfamily is 24 with both simple and multiple sex chromosome systems (Table 1). Considering the available cytogenetic characteristics of Reduviidae together with the results here presented the evolutionary karyotypic trends within the family were analysed.

#### MATERIAL AND METHODS

##### Specimens

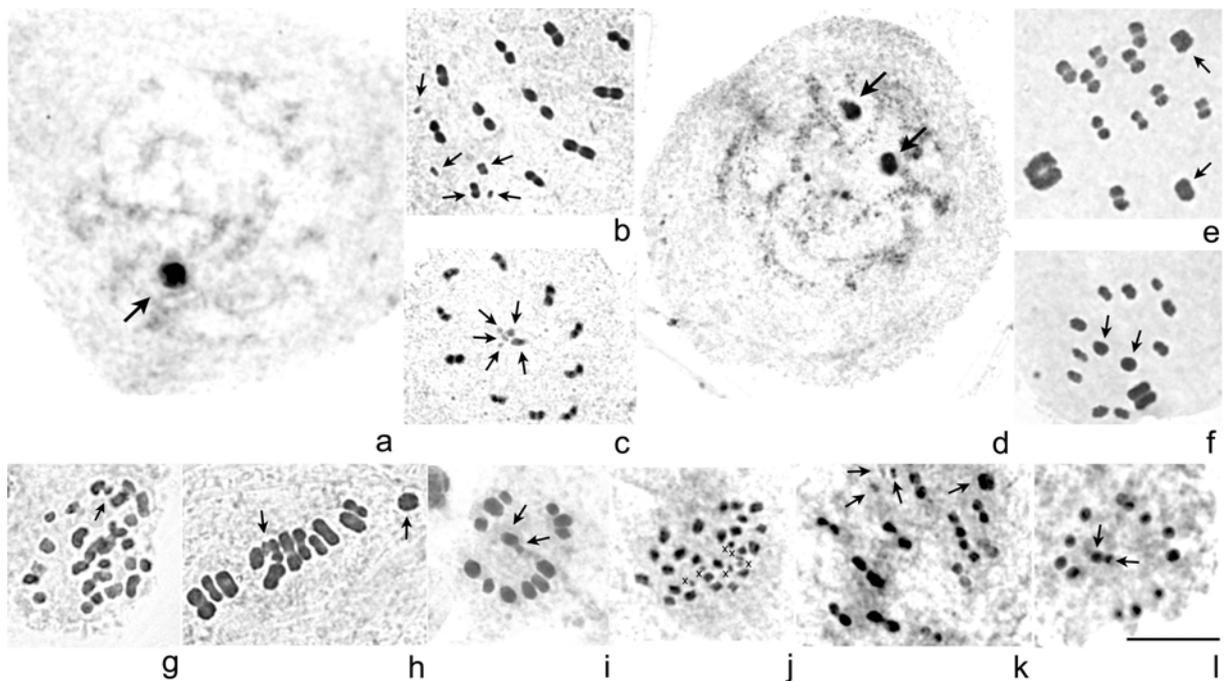

The number of male and female individuals of *Stenopoda cinerea* (Stenopodainae), *Apiomerus lanipes*, *Zelus* sp. prope *leucogrammus*, *Cosmoclopius nigroannulatus* and *C. poecilus* (Harpactorinae), and their provenance are indicated in Table 2.

##### Chromosome preparations

Some individuals were fixed in the field in 3:1 (ethanol:glacial acetic acid) and other specimens were brought alive to the laboratory. Gonads were dissected under a binocular microscope. Gonads fixed in 3:1 were used for slides by squash procedures and standard staining techniques (haematoxylin staining).

#### RESULTS

In the five species here analysed the male meiosis follows the general heteropteran pattern. During early prophase I the sex chromosomes are recognized because they are positively heteropycnotic. After pachytene the cells enter a diffuse stage during which the autosomes decondense completely. At diplotene the autosomal bivalents recondense, and in most species they present only one chiasma. At metaphase I the autosomal bivalents and the sex univalents arrange at the equatorial plane, and at anaphase I the sex univalents segregate equatorially, while the autosomes divide reductionally. At metaphase II the autosomes are arranged to form a ring and the sex

**Fig. 1, a-l.** **a-c** - *Stenopoda cinerea*; **a** - diffuse stage, **b** - metaphase I, **c** - metaphase II. **d-f** - *Apiomerus lanipes*; **d** - diffuse stage, **e** - metaphase I, **f** - metaphase II. **g-i** - *Zelus* sp. prope *leucogrammus*; **g** - spermatogonial prometaphase, **h** - metaphase I, **i** - metaphase II. **j-l** - *Cosmoclopius nigroannulatus*; **j** - oogonial prometaphase, **k** - metaphase I, **l** - metaphase II. Arrows show sex chromosomes. Bar=10  $\mu$ m.

chromosomes associate in a pseudobivalent or pseudomultivalent, which lies at the centre of the ring of autosomes and divides reductionally at anaphase II.

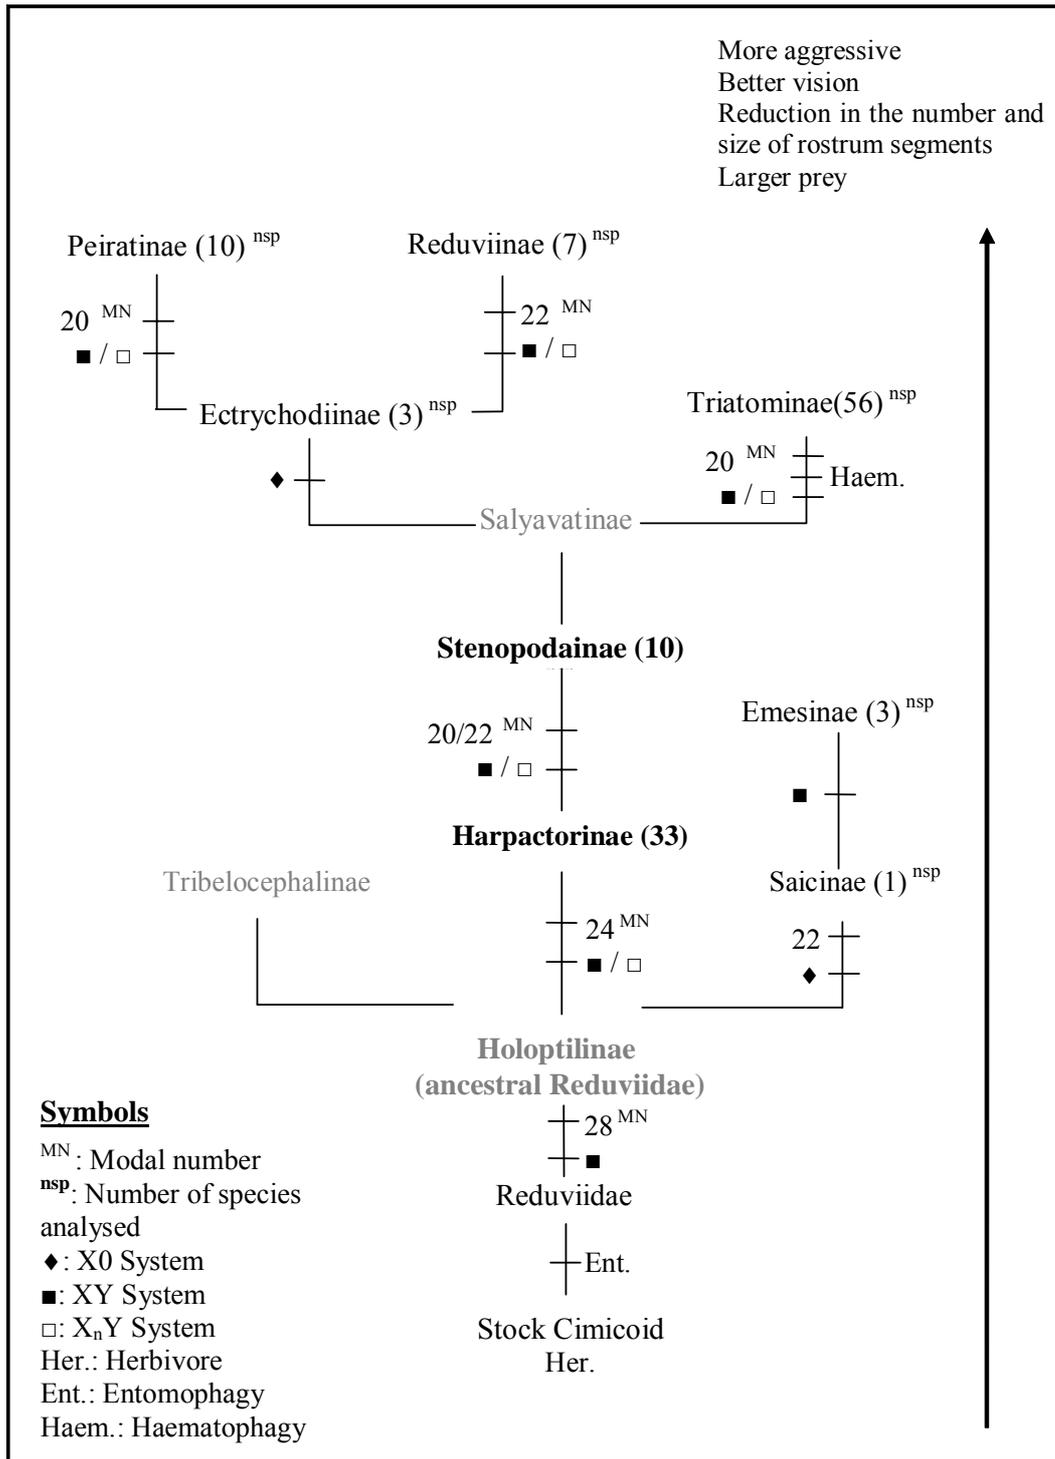

The presence and duration of the diffuse stage, the number and position of chiasmata and the arrangement of the autosomal bivalents and the sex univalents at metaphase I are features that differ among the species.

*Stenopoda cinerea* has  $2n=25=20+X_1X_2X_3X_4Y$  (male); autosomes decrease gradually in size and three out of the five sex chromosomes are very small. In the male meiosis of this species a long diffuse stage is observed (Fig. 1, a), bivalents present only one chiasma at terminal position, and at metaphase I the sex univalents are located at the periphery of the plate (Fig. 1, b). At metaphase II the sex pseudopentavalent lies at the centre of

the ring of autosomes (Fig. 1, c).

*Apiomerus lanipes* has  $2n=22+XY$  (male) (Fig. 1, d-f). Among the autosomes one pair is remarkably larger, and the X and Y sex chromosomes are the second largest, and similar in size. Male meiosis presents a long diffuse stage (Fig. 1, d), and at diakinesis each bivalent presents one chiasma at terminal position, except for the largest pair that shows two terminal/subterminal chiasmata. At metaphase I the eleven bivalents plus the X and Y univalents arrange disorderly at the equatorial plane (Fig. 1, e). At metaphase II the autosomes dispose in a ring, and the XY pseudobivalent lies at its centre (Fig. 1, f).

*Zelus* sp. prope *leucogrammus* presents  $2n=26=24+XY$  (male) (Fig. 1, g-i). The X chromosome is the smallest of the complement and the Y cannot be recognized at mitotic prometaphase

**Fig. 2.** Origin and evolution of the Reduviidae (modified from Ambrose, 1999) and cytogenetic characteristics of members of the family (modal autosomal diploid number, sex chromosome system and number of species cytogenetically analysed in each subfamily).

because it is similar in size to the autosomes. During male meiosis no diffuse stage is detected, and chromosomes do not show any particular arrangement at the first meiotic metaphase plate (Fig. 1, h); however, the metaphase II arrangement is the typical heteropteran one with the sex chromosomes associated in a pseudobivalent and in the centre of the autosomal ring (Fig. 1, i).

*Cosmoclopius nigroannulatus* and *C. poecilus* share the same cytogenetic characteristics and male meiotic behaviour. They have  $2n=28/30=24+X_1X_2X_3Y/24+X_1X_1X_2X_2X_3X_3$  (male/female) (Fig. 1, j-l). At spermatogonial prometaphase the sex chromosomes can be readily distinguished: the Y chromosome is the largest of the complement and the X chromosomes are the smallest ones. In female mitosis the six sex chromosomes are also easily detected (Fig. 1, j). In these species the diffuse stage is also very long, and at diplotene/diakinesis it is evident that autosomal bivalents present only one terminally located chiasma. At metaphase I the 12 autosomal bivalents generally dispose in a ring, and the sex univalents lie at its centre, although this arrangement is not always observed (Fig. 1, k). At metaphase II the sex multivalent is placed in the centre of the autosomal ring (Fig. 1, l).

#### DISCUSSION

With the present contribution, 127 species from 11 subfamilies of Reduviidae are now cytogenetically known; 56 of them belong to Triatominae (44.09%), 33 to Harpactorinae (25.98%), 10 to Peiratinae (7.87%) and 10 to Stenopodainae (7.87%). The remaining species (14.17%) are evenly distributed among other seven subfamilies: Bactrodinae (1 species), Ectrychodiinae (3), Emesinae (3), Hammacerinae (1), Phymatinae (2), Reduviinae (7) and Saicinae (1). No cytogenetic reports are available on species of the remaining eleven subfamilies (Ueshima, 1979; Manna, 1984).

The Stenopodainae are characterized by the

autosomal diploid number of 20/22 ( $n=10A/11A$ ) and multiple sex chromosome systems  $X_nY/X_nX_n$  (Table 1). *Stenopoda cinerea* constitutes the tenth species of the subfamily cytogenetically analysed and its chromosome number and male meiotic behaviour agree with previous reports in other species of the subfamily. It deserves attention that among the sex chromosomes three Xs are remarkably smaller than the remaining X and Y chromosomes.

Although Harpactorinae are the largest reduviid subfamily, only 33 species have been cytogenetically studied. The modal diploid autosomal number is 24 ( $n=12A$ ) and both simple and multiple sex chromosome systems are found (Table 1). Under the hypothesis that the modal karyotype probably represents the ancestral one, *Zelus* sp. prope *leucogrammus*, *Z. exsanguis* (Stål, 1862) and *Vesbius purpureus* (Thunberg, 1784) should represent the original karyotype of the subfamily ( $2n=24+XY$ ). On the other hand, *Apiomerus lanipes* shows a reduction in the autosomal number from 24 to 22; concomitantly, one autosomal pair is remarkably larger than the others suggesting that it has originated through an autosomal fusion. The five species of *Apiomerus* cytogenetically known are karyotypically similar suggesting that the autosomal fusion should be synapomorphic for the genus within Harpactorinae. Finally, *Cosmoclopius nigroannulatus* and *C. poecilus* show the modal diploid autosomal number of the subfamily and multiple sex chromosomes ( $2n=24+X_1X_2X_3Y$ ). The Y chromosome is strikingly large and completely heterochromatic, and the Xs are very small and of similar size.

Considering  $2n=24+XY$  as the ancestral karyotype of the subfamily, some evolutionary trends can be detected: reduction in autosomal number in some genera through fusion mechanisms, and fragmentation of the X chromosome to give rise to multiple sex chromosome systems. If multiple Xs have adaptive advantages cannot be as-

certained at present.

The other two subfamilies of Reduviidae cytogenetically more deeply analysed are Triatominae and Peiratinae. The Triatominae are highly homogeneous with 20 autosomes (only three species out of 56 have 18 autosomes, and one, 22). The sex chromosome mechanisms are principally XY/XX (52.54%) and  $X_1X_2Y/X_1X_1X_2X_2$  (44.07%), and just two species possess other  $X_nY$  mechanisms (Table 3). Within Peiratinae, the autosomal number is also 20; the most frequent sex chromosome system is XY, and three species have  $X_1X_2Y$  (Table 3) (Ueshima, 1979; Manna, 1984).

### Karyotype evolution in Reduviidae

Reduviidae together with Cimicidae are the two heteropteran families in which multiple sex chromosome systems of the  $X_nY$  type have reached their broadest distribution and variation. Thus, in

any discussion on karyotype evolution in these families the autosomal number and the sex chromosomes should be considered separately on behalf of a better understanding of the evolutionary trends.

Ambrose (1999) proposed a phylogeny on the origin and evolution of assassin bugs in which Stenopodainae might have evolved from the Harpactorinae, and the Peiratinae and Reduviinae should be considered as derived groups of aggressive predators (Fig. 2). According to this author, who analysed morphological characters, feeding habits, habitats and predatory behaviours of Reduviidae, the predaceous reduviids should have originated from the cimicoid ancestral stock characterized by herbivory and a four-segmented rostrum through saprophagy. During the course of evolution of carnivorous reduviids from the saprophagous cimicoid stock, the rostrum might have undergone reduction from four to three segments, and the shortening of the segments. The ancestral reduviids (Holoitilinae) were probably timid predators, which searched for small prey at random. From these timid predators such as holoitilines, emesines, saicines, tribelocephalines, stenopodaines and some harpactorines, aggressive reduviid predators or assassin bugs might have evolved gradually from Emesinae with poor vision to Harpactorinae with good vision. The salyavatines might have evolved from the aggressive harpactorines and stenopodaines, and represent the primitive predatory status, while Reduviinae represent the advanced predatory status. Ectrychodiinae that feed exclusively on millipedes (myriophagy) might have evolved from salyavatines, and Peiratinae might have also evolved from salyavatines in a different line adapted for entomophagy. Triatominae could have evolved from the Salyavatinae to haematophagy.

From a cytogenetic point of view the Cimicoidea have an autosomal diploid number of 28, and assuming that the ancestral diploid number for Reduviidae should have been the same (Holo-

ptilinae), the evolutionary trend within the family should have involved a reduction in autosomal number: 24 in Harpactorinae, 20/22 in Stenopodainae, 22 in Reduviinae, and 20 in Triatominae and Peiratinae (Fig. 2).

With respect to the sex chromosome systems it is generally agreed that multiple systems have originated from simple systems through chromosome fragmentations (Papeschi, 1996). In Reduviidae the frequency of the different systems (from  $X_1X_2Y$  to  $X_1X_2X_3X_4X_5Y$ ) is not homogeneously distributed among subfamilies (Table 3). Two species of Ectrychodiinae and the only species of Saicinae have an  $X0/XX$  system, with a pre-reductional male meiotic behaviour of the X chromosome, at least in the former species. The simple system  $XY/XX$  is present in 46.09% of the species and the remaining species show different degrees of X chromosome multiplicity:  $X_1X_2Y$  (32.82%),  $X_1X_2X_3Y$  (14.06%),  $X_1X_2X_3X_4Y$  (3.13%) and  $X_1X_2X_3X_4X_5Y$  (1.56%). From the 18 species with  $X_1X_2X_3Y$ , 14 belong to Harpactorinae and 3 to Stenopodainae; of the 4 species with  $X_1X_2X_3X_4Y$ , two belong to Stenopodainae, and the 2 species with  $X_1X_2X_3X_4X_5Y$  belong to Harpactorinae. It can be observed that the multiple systems are more frequent in Harpactorinae and Stenopodainae than in the other subfamilies.

The analysis of sex chromosome systems is also in agreement with the phylogeny proposed by Ambrose (1999). During karyotype evolution in Reduviidae some genera belonging to the different subfamilies, Emesinae, Harpactorinae, Stenopodainae, Peiratinae, Reduviinae and Triatominae, maintained the ancestral sex chromosome system  $XY/XX$ , while in other genera the original X fragmented giving rise to different multiple systems ( $X_nY$ ). Furthermore, in only three species of Ectrychodiinae and Saicinae a simple system  $X0$  is observed probably originated through the primary loss of the Y chromosome (Fig. 2).

Summarizing, two different mechanisms occurred during karyotype evolution of Reduviidae:

the reduction in autosomal number through fusions, and the increase in the number of sex chromosomes through fragmentations (multiple systems). Although the fragmentation of the X chromosome is a characteristic of the family, the phenomenon is far more frequent in Harpactorinae and Stenopodainae than in other subfamilies.
